Abstract
In recent years, there has been an increasing interest in getting planners to “execute” their plans in the real world. Among them, the temporal “partial order causal link” planner IxTeT has been endowed with a temporal executive, and has been successfully tested on an ATRV robot. Yet new problems arise from the fact that the plans are now being executed. In domains such as robot planning, many tasks have an uncertain duration (a move in a partially unknown environment takes an uncertain amount of time). The current solution is to use an interval constraint to represent the possible duration in a Simple Temporal Network. By doing this, the planner or the executive are allowed to reduce the possible durations by propagating other constraints. Hence, this reduction may lead to a plan execution failure. This problem, known as the “controllability” problem, as been addressed by a number of people. For example, the 3DC+ algorithm has been proposed to provide dynamic controllability. Yet to our knowledge, no implementation has been made showing the advantage of such approach. This paper presents the results we got using 3DC+ in IxTeT.

Having now a temporal planner which now “complies” with non controllable temporal constraints, we addressed a second problem which arises at execution time. IxTeT, being a least commitment planner, does not try to minimize the makespan. In fact, the default heuristic is tuned more to spread the actions over the given horizon (to minimize conflict) than to finish the job at the earliest. We implemented a new heuristic which keeps the least commitment strategy yet minimizing the makespan of the plan. This heuristic gives good statistical results on the model we use for our exploration rover type problem.

We have tested these two recent modifications on the robot, but also using a very accurate rover simulator. We present real results and simulated ones which show the improvement over the previous version/heuristic.

Introduction
Future rover exploration missions will require a high level of autonomy in order to achieve goals such as navigation beyond the visual range. On board task and activities planning should allow the rover to execute those plan autonomously and to react without needing a new plan to be uploaded from earth.

Actual robotic space exploration missions are very expensive, with a high requirement for quality scientific returns. During the MER mission, the use of MapGen (Ai-Chang et al. 2003) has allowed a 25% increase of such return (Rajan 2004).

During the past years some planners have proven their ability to handle complex situations required by autonomous systems. Some of these systems (e.g. RAXPS (Jonsson et al. 2000), CASPER (Chien et al. 2005)) have been deployed. Reasoning about time is necessary to address these planning problems. The planner must be able to take into account strict deadlines, temporal windows for some tasks, durative actions, and durative goals.

Many temporal formalisms were developed in the past years. The STN formalism is often used. The requests on these networks are solved very efficiently by polynomial algorithms. Nowadays, an extension to uncertain constraints has been studied and polynomial algorithms have been proposed.

In an autonomous planner, optimization can be made in two ways: finding directly a good plan or searching several plans to find the better one. Due to limited computational capacity, the second approach is often unreasonable. So we have to modify the planner to search for high quality solutions.

The IxTeT planner (Ghallab & Laruelle 1994) was developed to handle robotic planning problems. It was extended to handle complex resources (Laborie & Ghallab 1995), continuous constraints and constraints between both atemporal and temporal variables (Trinquart & Ghallab 2001). Further work (Lemai 2004) added a temporal executive to IxTeT. The resources management has been extended to handle continuous resources usage (Lemai & Ingrand 2004).

New issues were raised while experimenting with IxTeT new executive. Many plans failed because the executive or the planner reduced the allowed duration of some tasks. In

---

1Originally IxTeT was a temporal formalism (Ghallab & Mounir-Alaoui 1989) used to check consistency other qualitative temporal relations.

2STN: Simple Temporal Network

3IxTeT is a system used for chronicle recognition, planning and temporal execution.
fact, most of the tasks (move, communication, image compression, etc) have uncertain durations. So we decided to implement an existing temporal formalism with explicit uncertainties (STNU). The planner produces temporal contingent plans, i.e., plans that do not fail because of a reduction of an uncertain duration.

Another issue is that while executing the plan, the robot often remains inactive. In fact, the plans produced with a least commitment heuristic may contain unjustified wait periods. Though, they may be necessary to adapt the plan during execution, they reduce the performance of the overall system. This raises a need for plans with a shorter makespan. We solve this problem by modifying the planning heuristic.

These new contributions must be validated by experimental returns. Previous works (Lemai 2004) have integrated the planner in the controlling architecture of an autonomous rover. Nevertheless, the experiments with a real robot take a lot of time, so we integrated IxTeT to a simulated rover controlling architecture to make extensive tests. This simulator allows us to make accurate comparisons between the modified versions and the old one.

During the analysis of the results, we identified a drawback of the plan repair mechanism. We propose a solution to it by modifying the way the plan are repaired. This is an ongoing work and some preliminary results are shown.

This paper is organized as follows. The first and second sections describe the IxTeT planner and the temporal executive. The third one describes the validation scenario and the fourth describes the experimental results. The last section introduces some work on improving the plan repair method. We conclude the paper with a discussion and outlooks.

The IxTeT Planner

Plan-space Search

IxTeT is a temporal constraint-based causal link planner. It uses CSP techniques\(^4\) to maintain the consistency of the plan constraints. In particular, the planner is using a Simple Temporal Network (Dechter, Meiri, & Pearl 1991) for the temporal constraint.

The plan is represented by state variables ranging over finite symbolic and numerical domains. These plans use chronicles (Ghallab, Nau, & Traverso 2004) to describe the world, its evolution and the planning problem. The explicit representation of the time permits to have temporally extended goals, durative actions and rendez-vous or visibility windows.

Definition 1 A temporal assertion on a state variable \(v\) is either an event or a persistence condition on \(v\).

- An event, denoted \(x@t : (v_1, v_2)\), specifies an instantaneous change of the value of \(x\) from \(v_1\) to \(v_2\) at time \(t\), with \(v_1 \neq v_2\).
- A persistence condition, denoted \(x@[t_1, t_2] : v\), specifies that the value of \(x\) persists as being equal to \(v\) over the interval \([t_1, t_2]\).

In any temporal assertion, \(v, v_1\) and \(v_2\) can be defined by atemporal variables. \(t, t_1\) and \(t_2\) are temporal variables.

Definition 2 A chronicle for a set of state variables \(v_1, v_2, \ldots, v_n\) is a pair \(\Phi = (F, C)\), where \(F\) is a set of temporal assertions about the state variables \(v_1, v_2, \ldots, v_n\) and \(C\) is a set of constraints on variables used in the chronicle.

Definition 3 A plan \(P(S, \Phi, G, CA, F, T)\) is described by the state variables contained in \(S\). \(\Phi\) is a chronicle describing all the temporal assertions of the plan. \(F\) is the set of defaults in the plan. \(CA \subset \Phi\) contains temporal assertions on variable of \(S\) describing the predicted evolution of contingent attributes. The goals are in \(G \subset \Phi\). They are temporal persistence conditions on state variables of \(S\). \(T\) is the set of tasks in the plan.

The planner begins with a plan describing the initial situation, the initial goals of the problem and the known predicted evolutions of contingent attributes such as visibility windows. The search is performed until the plan contains no default. These defaults are temporal assertions unexplained in the current plan\(^5\), conflicts between two temporal assertions or possible resource conflicts. At each search step, a default is chosen. One of the resolvants of this default is then applied.

The search toward a solution is performed using a dynamic abstraction hierarchy (Garcia & Laborie 1995) on the attributes of the planning domain. The hierarchy provides a dynamic ordering on the resolution of the defaults in the plan. This ordering can dramatically improve the speed of the planner.

The heuristic computes a cost for each resolver of each default. Then, it chooses the next default to solve \(\rho\) using an opportunistic strategy. A default is preferred if it has less resolvants than the other and if it is easier for the planner to choose one among them. The cheapest resolvant is then chosen. The choice is considered as easier for example if one resolvant cost is 0.1 and the other cost is 0.9. We have a better confidence in the automated choice if the difference between costs is high.

The goal of the IxTeT heuristic among other partial order planner heuristics (Pollack, Joslin, & Paolucci 1997; Younes & Simmons 2003) is to reduce the size of the search space. The IxTeT heuristic tries to preserve the flexibility in the plan in order to reduce the number of backtracks. It explains why plans may be suboptimal.

\[
\text{Opp}(\rho) = \sum_{r \in \text{resolvant}(\rho)} \frac{1}{1 + \text{cost}(r) - \text{cost}_{\text{min}}(\text{resolvant}(\rho))}
\]

Theoretically, the commitment of one resolvant is computed by estimating the number of completely instantiated reachable solution plans removed by the resolvant \(r\). In fact, estimation were developed. A complete description of the cost functions can be found in (Lemai 2004).

We have implemented a new version of the heuristic with two modified costs. The first considers one single ordering

\(^4\) Constraint Satisfaction Problem (Mackworth 1977) (CSP)

\(^5\) A temporal assertion is not explained by a plan if it is not an initial condition or if no causal link establishes the assertion.
The new cost is the sum of the equality constraints and the cost of the persistence condition. The temporal cost is ignored even if the constraint is necessary. This allows the heuristic to order the causal links only by their respective durations.

We modified the cost of the persistence condition. The new cost is the ratio of the maximum duration of the persistence condition on the maximum duration of the plan. The new cost uses the maximum duration. It represents possible negative effects of causal link with a possible big upper bound on the duration.

### Underlying CSPs

**Definition 4** A CSP (Mackworth 1977) \( \Gamma = (V, D, C) \) is defined by \( V = \{ v_i \mid i = 1, \ldots, n \} \) the set of all variables, \( D = \{ d_i \mid i = 1, \ldots, n \} \) the set of variable domains. Finally, \( C = \{ c_{ij} \mid i = 1, \ldots, p \} \) is the set of constraints on variables contained in \( V \).

IxTeT uses classical CSPs algorithms for managing constraints on atemporal variables. It uses an STN for managing all the temporal constraints.

In some cases, one wants to link the effects of a task to its duration. For example, if the consumption of a resource depends on the duration of the task, you need a mixed constraint between temporal and atemporal variables. IxTeT features a mechanism (Trinquet & Ghallab 2001) to propagate these constraints.

For example, let \( t \) be a navigation task of expected duration \( d \). The speed of the robot is represented by the variable \( s \) and the length of the navigation by \( l \). The mixed constraint \( c_{ts} \{ d * s = l \} \) links the duration of the task to the length of the trajectory.

**Definition 5** An STN (Dechter, Meiri, & Pearl 1991) \( \Theta = (V, D, C) \) is a restricted form of CSP. \( V = \{ v_1, \ldots, v_n \} \) is the set of variables. \( D = \{ d_i \mid \forall i \mid d_i = \mathbb{R} \} \) is the set of variable domains. \( C \) is the set of constraints on variables contained in \( V \). The constraints are all of the form: \( lb \leq v_i - v_j \leq ub \) which is equivalent to \( v_i = v_j \in [lb, ub] \)

On the STN, IxTeT uses a path consistency algorithm like PC-2 (Mackworth & Freuder 1985) that is able to compute the minimal network of an STN (thus removing all values not belonging to a solution). The time complexity is \( O(n^3) \) for the complete algorithm and an incremental one\(^7\) is only in \( O(n^2) \). During planning, the planner uses the incremental algorithm. During a nominal execution, the same algorithm is used to propagate instantiations of action start and end timepoints. If a temporal failure invalidates some temporal constraints, a relaxation is done by removing the failed constraints and by regenerating all the remaining constraints with the complete algorithm.

It is possible to use a fast algorithm (Muscettola, Morris, & Tsamardinos 1998) for STN execution. It is based on the property of dispatchability. However it is much efficient than using an \( O(n^2) \) algorithm, we cannot use it because

---

\(^6\)Tests have been made with \( t_1 \) without significant differences.

\(^7\)If only one constraint of the STN is restricted, the incremental algorithm can be used.
the propagation of mixed constraints needs a complete algorithm.

**Simple Temporal Network with Uncertainties**

**Definition 6** An STNU (Vidal & Fargier 1999) $\Theta = (V, D, C_{clb}, C_{ctg})$ with $V$ the set of variables, $D$ the set of domains. These definitions are the same than the STN ones. The set $C_{clb}$ is all the controllable constraints equivalent to STN constraints. $C_{ctg}$ is a set of uncontrollable constraints of the form $lb \leq v_i - v_j \leq ub$. The duration of this constraint can only be observed.

The introduction of not controllable constraints changes the consistency notion inherited from the STN. Three main levels of controllability have been defined (Vidal & Fargier 1999). Schematically, an STNU is weakly controllable if the execution controller needs to know all the uncontrollable durations before executing the plan. An STNU is strongly controllable if the execution controller instantiates the controllable timepoint at the same time whatever the observed uncontrollable durations are. Finally, an STNU is dynamically controllable if the execution controller must take decisions knowing only the past observations and timepoint instantiations. Finally an STNU is pseudo-controllable if it is consistent and no uncontrollable durations are squeezed (Morris, Muscettola, & Vidal 2001).

The two possible choices are dynamic or strong controllability. The two possible properties can be checked in polynomial time. The first one is more flexible and may have a lower makespan$^3$. The second one has a lower complexity during execution. This controllability is more restrictive than the dynamic one, fewer STNUs are strongly controllable. We decided to experiment the dynamic controllability due to these advantages.

Each triangle (see Fig.2), a test is performed in order to identify the possible necessary constraints to enforced dynamic controllability. Four cases exist:

- In the case where $C$ necessary follows $B$, nothing new is needed.
- In the case where $C$ necessary precedes $B$, a new constraint on $AC$ is needed : $(C - A)$ in $[y - v, x - u]$.
- In the other cases $C$ and $B$ are unordered. If $y - x \leq v$ then we must add the constraint $(C - A)$ in $[y - v, +\infty[$.
- Otherwise, a new type of constraint called “wait” is needed: $< B, y - v >$. It means that before executing $C$ you must wait $y - v$ after the execution of $A$ or the observation of $B$.

At the start of each cycle, the APSPG$^9$ is computed. Then, the new necessary constraints are added. After the analysis of all triangles, the algorithm propagates all the waits to ensure they will be never broken during execution. The termination condition is reached if the network is not pseudo-controllable or if no new constraint has been added.

We have made two little improvements to this algorithm. The first concerns the fact that we want to incrementally maintain an STNU dynamically controllable during planning. Before the planner adds a new constraint to the network, our algorithm removes all existing waits. This is due to the fact that some of them are no more necessary due to the new constraint. More work is needed to find a better removal criterion.

The original algorithm performs several complete propagation with a complexity of $O(n^3)$ in order to test the property of pseudo-controllability. We have replaced this by maintaining always the network pseudo-controllable by incrementally propagating all addition of STN constraints during enforcement of dynamic controllability. If we suppose that $k$ constraints are added during a cycle, the complexity is in $O(kn^2)$. Experimentally, we observed that $k$ is rather constant. Yet the maximum bound of $k$ is in $O(n)$, the maximum number of uncontrollable constraints is $n - 1$.

**Autonomous Plan Execution**

**Temporal Plan Execution**

During execution, IxTeT controls the beginning, ending and interruption of tasks running on board the rover, by sending commands to the robot. The executive begins with an initial plan produced by the planner. This section of the paper briefly summarizes the work described in (Lemai 2004).

IxTeT executes the plan following a cycle. If a new event is received, it updates the plan. After that, if needed, a plan repair process occurs. At the end, it converts the executable timepoints into commands and updates the plan accordingly. The cycle has an expected maximal duration denoted $\mu$.

$^3$If all the uncontrollable durations are equal to their upper bounds, enforcing dynamic controllability makes a plan with a makespan equal to the one produced by enforcing the strong controllability. Otherwise, dynamic controllability is more time efficient.

$^9$APSPG: is the All Pairs Shortest Path Graph of the STNU. If one uncontrollable duration is squeezed, then the STNU is not pseudo-controllable and thus not dynamically controllable. Our implementation uses a PC-2 algorithm (Mackworth & Freuder 1985) with a complexity of $O(n^3)$. 

---

Figure 2: Basic constraint triangles analyzed by 3DC+. The left triangle is used when searching for new necessary constraints. The right one is checked during the propagation of a new ternary constraint called a “wait”.

The algorithm 3DC+ (Morris, Muscettola, & Vidal 2001) checks if an STNU is dynamically controllable. It is polynomial in time, computes the minimal graph and the most flexible one. It is complete and correct. It allows to produce plans and to safely execute them.

The algorithm performs several cycle of checking on triangles containing at least one uncontrollable constraint. On
For simplicity, the executive only considers the start timepoint \( t_{\text{start}} \) and the end timepoint \( t_{\text{end}} \) of tasks.

Typically, the system starts a task \( t(t_{\text{start}}, t_{\text{end}}, T, P) \) as soon as possible if its first timepoint \( t_{\text{start}} \) is executable and the actual plan supports its execution.

The system only interrupts tasks that can be preempted. Other tasks report their termination by sending a message summarizing the exact result of their execution.

In general, the system decides to interrupt a task \( t(t_{\text{start}}, t_{\text{end}}, T, P) \) when the current time \( u > t_{\text{end}} \) or if the plan is no more valid. If the task is controllable and the plan still remains valid, the decision will be made at:

- **Early time**: \( u_{\text{early}} \geq t_{\text{lb}}^{\text{end}} \) if the task is an early preemptive one.
- **Late time**: \( u_{\text{late}} = t_{\text{ub}}^{\text{end}} - \mu \) if the task is a late preemptive one.

The executive has to check the validity of the task reports considering the current plan. If the task has modified the level of resources, the executive checks for possible future conflicts. If the report is not nominal, it is considered as a task failure report.

### Unexpected Events During Execution of a Plan

The system may receive messages of new goals to satisfy, changes of resource capacity or task failures.

IxTeT integrates these messages into its current plan. During this insertion, it partially invalidates the current plan by removing some causal links and some temporal constraints. If the new plan is not valid, execution is immediately aborted. Otherwise it always tries to make local plan repair in order to restore the plan correctness.

The plan repair search is similar to the plan search, but it is interrupted by a maximum time empirically defined before execution.

IxTeT interleaves the plan repair process with perception of new events and new decisions. During this, the system has to always keep a valid plan to integrate new events or to execute something at each interrupt of the plan repair.

The plan repair process can fails in two cases. The first is when there is no correct plan in all the search space. The second case is when a time failure occurs before finding a new plan. These time failures correspond to the impossibility to instantiate a temporal variable corresponding to the beginning of an action, or a goal. These failures occur when the current plan repair process does not yet find a plan supporting the task. If the plan repair process fails, all the running actions are interrupted and a complete replanning is done.

When a complete replanning is needed, the system builds a new initial plan containing the current state and the remaining predicted evolution of contingent state variables. The remaining goals are kept.

During the search, at each step of the planning process IxTeT verifies that enough time remains for executing the plan. This is done by adding to the plan a temporal variable corresponding to the end of the replanning. All new inserted tasks are constrained to occur after this temporal variable. If the upper bound of the special variable is lower than the actual time minus a constant time needed to initialize the executive, the search is stopped.

When a replanning fails, the system abandons one goal. The goals are ranked according to a fixed priority value. The goal or one of the goals with the fewer priority is suppressed. A new replanning attempt is made until a solution plan is found. The abandoned goals are reinserted before any new complete replanning, and if their temporal constraints are still valid. A goal is retried only one time.

### The Experimental System

#### The Simulated Architecture

IxTeT runs on the robot Dala (see Fig.3) and on a simulator of this robot. The simulator allows us to perform accurate tests of the different IxTeT strategies presented in the paper. The environment and the initial conditions are exactly the same.
In the top of the simulated functional layer, there is OpenPRS (Ingrand et al. 1996). It is used for actions monitoring and refining of the high level tasks into low level commands.

**Evaluation Scenario**

The main goal of the scenario is to evaluate the new modifications of IxTeT. A typical mission is defined as part of the evaluation scenario. The mission is then instantiated with different parameters to test the stability of the results.

**Typical Mission**

This is an exploration rover like mission. The robot must acquire scientific data from several places. During its mission, it has to communicate with an orbiter during visibility windows. It has to be at a specific location at the end of the mission (for example back at its starting point).

For the need of the demonstration, we add a constraint on the motion of the cameras\(^{10}\) (i.e. the MOVE_PAN_TILTUNIT task, see Fig.7) to heat the motors before using them. The power constraints are such that heating is compatible with motion of the robot.

On the robot, the cameras are mounted on a pan and tilt unit.

The MOV\_PAN_TILTUNIT task

**Different Configurations Tested**

IxTeT now features two different planning heuristics and two different time management systems. This defines four IxTeT instantiations.

Four different worlds have been defined. The first one has no obstacle. The second and the third ones each contain three obstacles. The last world contains all the obstacles in worlds two and three.

We have tested some goals configurations and some temporal window specifications. The values have been chosen randomly.

**Results**

**The Makespan:**

The new heuristic produces shorter initial plans with 3DC+ or without. During execution, the planner may need to repair several times the plan leading to a suboptimal plan containing unnecessary tasks.

Plans produced with the new heuristic are not always shorter than plans produced with the old one. The IxTeT planner does not have any geometric reasoning capacity. Thus, the plans produced are seldom optimal in the length of the planned path for the rover.

There is also the possibility that the ordering between navigations and communications is inefficient w.r.t. the global makespan, because the solution plan depends on ordering choices made early during the planning process. IxTeT does not choose the path of the robot in a way that minimize the wait periods before communications, however it can efficiently order the existing navigations and the communications.

The usage of 3DC+ makes plans longer than with an STN, but this point is also relative to robustness as discussed in the next part.

**The Robustness:**

The usage of STNU and dynamic controllability is a real improvement. In our tests (approximately 250 runs), with 3DC+ all goals were achieved except in one run. In runs without 3DC+, the system achieves only 50% of the goals.

Another big advantage is that plans are safer. Indeed when not using 3DC+ it may produce unexecutable plans. The effect is that some unachievable goals are not canceled when needed. It leads to failures to execute the higher priority goals instead of lower ones.

The usage of the new heuristic is catastrophic when used without 3DC+. It comes from the fact that task durations are squeezed and lead to almost systematic plan failures.
Figure 5: Typical initial plan of the robot during our experiment using an STNU as time formalism and using the makespan minimizing heuristic.

The new heuristic does not give bad results when used with 3DC+. This is due to uncertainties that make a less compressed schedule than with an STN which is a good property, from the point of view of robustness.

Planning Duration and Other Time Measures: On small problem (≤ 5 scientific goals plus two communications), the planning time is similar. There is no significant difference using one heuristic or the other. In our tests, the problems are always easy due to needed flexibility (in order to have time for new goals). So this heuristic has not been tested on hard problem. Yet, the usage of a complex world representation (numeric domains and actions effect depending of the duration of the task) makes it harder to prove that a planning problem has no solution even using the old heuristic.

The use of 3DC+ implies a higher temporal complexity at each planning and execution step. But contrary to the worst case, with a good implementation of the algorithm, the added cost is acceptable. During execution, the instantiation of a “task start” or “stop” takes 0.001 s with an STN and no more than 0.01 s with an STNU. The duration of plan repair steps are about 3 times longer with an STNU. These results show that the cost of 3DC+ is compatible with its usage on an autonomous robot.

Prospectives and Current Work
During our test, we identified a drawback of the current plan repair process of IxTeT. Sometimes, a repaired plan contains unnecessary or unoptimal tasks. For example, during our tests, we add new “TAKE_PICTURE” goals. The planner produces a plan resulting in going back and forth from an existing waypoint to a new goal location. This may lead to a very low quality plan.

This situation arises when a new unsatisfied goal is added directly or during plan repair. This unsatisfied goal must not yet be an establisher of any temporal assertion in the plan. This goal must be on a state variables which has to take at least three different values (e.g. the position of the robot).

During the plan repair process, the planner establishes the new goal. If this goal is satisfied after any temporal assertion in the original plan, all is good. In the other case, the planner must insert tasks to reestablished the precedent values of the state variables. These tasks may be unnecessary, or their insertions impossible. The fig.8 illustrates the problem with a navigation.

A Basic Solution
We describe this work using an example run. It is a mission with initially 5 “TAKE_PICTURE” goals and 2 “COMMUNICATE” goals. The initial plan is found in 1.7 s. It contains 22 tasks, 90 atemporal variables and 75 temporal variables. One “TAKE_PICTURE” goal is added during the first communication.

The problem illustrated on fig.8 comes from a limited relaxation of the plan before the plan repair process. The solution described in the precedent sections of this paper, removes only causal links. A planner like IxTeT, adds constraints on variables to make causal links valid. If these constraints remain, the plan repair produces a suboptimal solution. The solution is to remove the constraints at the same time than the link.

We integrated the algorithms described in (Surynek & Bartáš 2004; Bartáš & Surynek 2005). We adapt the first one to continuous domains and use it to manage the filtering in the atemporal CSP. This permits to remove the atemporal constraints supporting a causal link.
Figure 6: Typical initial plan of the robot during our experiment using an STNU and the commitment minimizing heuristic.

```

TAKE_PICTURE(OBJ2,4,0)
COMMUNICATE(W2)
MOVE(4,0,0,0)
MOVE_PAN_TILT_UNIT(STRAIGHT,AT_MY_FEET)
TAKE_PICTURE(OBJ1,0,0)
```

Figure 7: An example of move and camera orientation (the cameras are mounted on a pan&tilt unit).

The temporal constraints are not removed because the result is not satisfying. The main reason is that the planner introduces many more temporal constraints for solving conflicts between two temporal assertions than for justifying causal links. Relaxing only the constraints associated with causal links does not significantly relax the plan contrary to atemporal constraints.

We made another modification to the precedent algorithm. The executive selects all the causal links that may prevent the planner from finding a solution. It removes from this set the causal links that were added to justify a task. Precisely, during planning, the planner adds tasks to justify unestablished temporal assertions. The new task is then linked to the temporal assertion by a causal link. The final set is about 41 causal links in our example run.

We have tried our solution using the simulator and the repaired plan is similar to the one illustrated on fig.9. The time needed to remove constraints is negligible: 0.02 s for 21 constraints. The planner finds a solution containing only necessary tasks or navigations. The duration of plan repair is approximately 1.2 s for a plan with five “TAKE_PICTURE” goals plus a new one. The needed relaxation of the mixed constraints takes about 1.5 s. This is longer than a complete replanning but it keeps the plan more stable and allows the system to execute valid part of the plan.

This solution is yet limited to simple cases where actions partial order allows the planner to find a new solution. In the next part we discuss a solution to this limitation.

A Future Work

Actually, we store the constraints associated to causal links. We are able to produce better plans using plan repair. We lack the capacity to change the order between tasks. In a typical mission, communications are made during fixed temporal windows while navigations are free. If we want the plan repair process to be complete, we must be able to move navigations around communications.

This may be done by storing which constraints have been inserted to solve conflict between temporal assertions. The information is associated with each involved assertions. If a plan repair process is needed, the executive removes only the constraints associated to temporal assertions of not yet executed tasks.

constraint and the atemporal one. This leads to a complete propagation of the STN.

11 A mixed constraint is relaxed by removing both the temporal
Conclusion

We have described a temporal planner and executive whose plan execution raises new issues.

The first one is to deal with uncontrollable durations. We use a temporal framework with explicit uncertainties.

The second one is the bad quality of the plans when compared with a time optimal plan. We modify the search control of the planner to find better plans by modifying the planning heuristic.

A simulation architecture is used to evaluate the two solutions. An evaluation scenario is described and used to acquire results.

During the test, the heuristic has shown a good robustness. Yet, an identified drawback limits the performance of this work. A solution using the plan repair ability of IxTeT is briefly described in the last part of the paper.

The integration of an STNU shows that it is usable on a rover, contrary to the worst time complexity of $O(n^5)$ (Morris & Muscettola 2005), with $n$ the number of temporal variables. It shows a better robustness of the execution of the mission. If one goal is achievable, with 3DC+, it is executed.

But clearly, 3DC+ algorithm lacks the capacity to handle dynamic STNU. Some work have been made in this way (Stedl & Williams 2005). Yet to our knowledge, more work is needed to handle constraint removals.

References

It is a slightly modified version of 3DC+ with a cutoff mechanism.
